ABSTRACT

Background

Preterm infants are born with low skeletal stores of calcium and phosphorus. Preterm human milk provides insufficient calcium and phosphorus to meet the estimated needs of preterm infants for adequate growth. Supplementation of human milk with calcium and phosphorus may improve growth and development of preterm infants.

Objectives

To determine whether addition of calcium and phosphorus supplements to human milk leads to improved growth and bone metabolism of preterm infants without significant adverse effects.

Search methods

We used the standard search strategy of the Cochrane Neonatal Review Group to search the Cochrane Central Register of Controlled Trials (CENTRAL; 2016, Issue 3), MEDLINE via PubMed (1966 to 14 April 2016), Embase (1980 to 14 April 2016) and the Cumulative Index to Nursing and Allied Health Literature (CINAHL; 1982 to 14 April 2016). We also searched clinical trials databases (11 May 2016) and the reference lists of retrieved articles for randomised controlled trials and quasi-randomised trials.

Selection criteria

Randomised and quasi-randomised trials comparing supplementation of human milk with calcium and/or phosphorus versus no supplementation in hospitalised preterm infants were eligible for inclusion in this review.

Data collection and analysis

Two review authors (JB, JW) independently extracted data and assessed trial quality using standard methods of the Cochrane Neonatal Review Group. We reported dichotomous data as risk ratios (RRs) and continuous data as mean differences (MDs) with 95% confidence intervals (CIs). We used the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach to assess the quality of evidence.

Main results

This is an update of a 2001 review that identified no eligible trials. One trial including 40 infants met the inclusion criteria for this review. Using GRADE criteria, we judged the quality of the evidence as low owing to risk of bias (inadequate reporting of methods of randomisation, allocation concealment and/or blinding) and imprecision (wide confidence intervals and data from a single small
We found no evidence of a difference between calcium and phosphorus supplementation versus no supplementation for neonatal growth outcomes (weight, length, head circumference) at any time point reported (two, four or six weeks postnatal age). At six weeks postnatal age, supplementation with calcium/phosphorus was associated with a decrease in serum alkaline phosphatase concentration (MD -56.85 IU/L, 95% CI -101.27 to -12.43; one randomised controlled trial (RCT); n = 40 infants). Investigators provided no data on growth at 12 to 18 months, neonatal fractures, feed intolerance, breastfeeding or any of the prespecified childhood outcomes for this review (fractures, growth, neurodevelopmental outcomes).

**Authors’ conclusions**

We identified one small trial including only 40 infants that compared supplementation of human milk with calcium and phosphorus versus no supplementation in hospitalised preterm infants. We judged the evidence to be of low quality and found no evidence of differences between groups for clinically important outcomes including growth and fractures. Although serum alkaline phosphatase concentration was reduced in the group receiving supplementation at six weeks postnatal age, this difference is unlikely to be of clinical significance. We conclude that evidence is insufficient to determine whether benefit or harm ensues when human milk is supplemented with calcium and/or phosphorus for the hospitalised preterm infant. We see no advantage of conducting further trials of this intervention because with the advent of multi-component human milk fortifier, supplementation of human milk with calcium and/or phosphorus alone is no longer common practice. Future trials should consider assessing effects of multi-component fortifiers with different mineral compositions on clinically important outcomes during the neonatal period and in later childhood.

**PLAIN LANGUAGE SUMMARY**

Does supplementation of human milk with calcium and phosphorus improve growth and development in preterm infants?

**What is the issue?**

When babies are born too early (preterm), they have very low stores of the minerals calcium and phosphorus needed for healthy bones and growth. Human milk may not contain sufficient minerals for these babies.

**Why is this important?**

Calcium and phosphorus are essential for healthy bones and normal growth and development. When a baby is born preterm and does not receive enough calcium and phosphorus, bone fractures and poor growth can occur.

**What evidence did we find?**

We searched for evidence in April 2016 and identified one randomised controlled trial including 40 babies. Investigators reported a small decrease in the concentration of alkaline phosphatase (an enzyme involved in bone growth) among infants who had received calcium/phosphorus supplementation. We found no difference in growth between infants who had been given human milk supplemented with extra calcium and phosphorus and infants who had received no supplementation. One small trial provided the evidence, and we judged the evidence to be of low quality. Researchers reported no follow-up of these babies into childhood.

**What does this mean?**

Evidence is insufficient to allow a judgement as to whether extra calcium and/or phosphorus provided to preterm babies confers benefit for their bones and growth. It is no longer very common to give calcium and phosphorus supplements alone, as human milk fortifiers now available include many other components as well as minerals to support the growth and development of preterm babies. We therefore suggest that future trials conducted to examine effects of mineral supplements in preterm babies include them in multi-component human milk fortifiers and assess clinically important outcomes into childhood.
### Summary of Findings for the Main Comparison

Calcium supplementation compared with no calcium supplementation for preterm infants

**Patient or population:** Preterm hospitalised infants  
**Setting:** Hospital setting  
**Intervention:** Calcium and/or phosphorus supplementation  
**Comparison:** No supplement

**GRADE Working Group grades of evidence**

- **High quality**: We are very confident that the true effect lies close to the estimate of effect
- **Moderate quality**: We are moderately confident in the effect estimate: The true effect is likely to be close to the estimate of effect but may be substantially different
- **Low quality**: Our confidence in the effect estimate is limited: The true effect may be substantially different from the estimate of effect
- **Very low quality**: We have very little confidence in the effect estimate: The true effect is likely to be substantially different from the estimate of effect

**Risk of bias:**
- Insufficient evidence to judge methods of randomisation, allocation concealment or blinding of personnel - downgraded one level
- Wide confidence intervals and data from a single small study - downgraded one level
- Evidence from a single small study - downgraded one level

BACKGROUND

Description of the condition

Human milk is the recommended nutritional source for full-term infants during at least the first six months of postnatal life (http://www.who.int/nutrition/topics/exclusive_breastfeeding/en/). For this group, breast milk supplies adequate substrate to meet the infant’s nutritional demands and provides the infant with other substances that may afford some physiological advantage (e.g., immunoglobulins, gastrointestinal hormones). Breastfeeding may also contribute to maternal-infant bonding.

Description of the intervention

Human milk is recommended for enteral feeding of all preterm infants (American Academy of Pediatrics 2014). However, human milk provides insufficient quantities of various nutrients, including calcium and phosphorus, to meet the estimated needs of these infants. Two-thirds of fetal body mineral content is acquired during the third trimester of pregnancy (Itani 1991). Therefore, preterm infants are born with low skeletal stores of calcium and phosphorus and require very high quantities of these minerals if they are to attain adequate postnatal skeletal growth. These requirements may not be met by feeding human milk alone (Bhatia 2007). Observational studies have shown that preterm infants fed human milk alone may have hypophosphataemia (Atkinson 1983), radiological evidence of poor bone mineralisation (Atkinson 1983; Rowe 1979) and elevated alkaline phosphatase activity (Rowe 1984), and all of this may be associated with fractures and lower than expected growth rates (Bhatia 2007). Furthermore, early bone mineral content may predict peak bone mineral density and therefore lifelong fracture risk (Winsloe 2009). On the other hand, calcium and phosphorus supplements can be associated with adverse effects such as hypercalcaemia, feed intolerance (Bozzetti 2009) and elevated calcium, all of which are associated with nephrocalcinosis and renal damage in preterm infants (Schell-Feith 2010). Concern about development of metabolic bone disease might lead parents and clinicians to give formula rather than persisting with expressing and giving breast milk when such a decision is considered. For this reason, provision of supplements might influence the likelihood of continued breastfeeding and hence developmental outcomes.

How the intervention might work

Supplementation of human milk with calcium and phosphorus may improve body mineral stores and maintain or improve bone metabolism while improving growth.

why it is important to do this review

We conducted this review to establish whether supplementing human milk with calcium and phosphorus leads to improved bone metabolism and growth outcomes for preterm infants.

OBJECTIVES

To determine whether addition of calcium and phosphorus supplements to human milk leads to improved growth and bone metabolism of preterm infants without significant adverse effects.

METHODS

Criteria for considering studies for this review

Types of studies

We included randomised controlled trials (RCTs) and quasi-RCTs, including cluster-randomised trials but not cross-over trials (inappropriate study design). We included both published and unpublished studies and studies published only as abstracts, if assessment of study quality was possible and if they fulfilled other criteria for inclusion.

Types of participants

Preterm infants (< 37 weeks gestational age) receiving care within a hospital setting.

Types of interventions

Randomised controlled trials comparing human milk supplemented with calcium and/or phosphorus versus unsupplemented human milk.

Types of outcome measures

Primary outcomes

• Growth to discharge (including weight and z score, length and z score, head circumference and z score)
• Growth at 12 to 18 months (including weight and z score, length and z score, head circumference and z score)
• Bone metabolism (including serum alkaline phosphatase (ALP), bone mineral content (BMC), timing defined by the trialist)
Secondary outcomes

Neonatal outcomes
- Incidence of fractures
- Adverse effects including significant hypercalcaemia (> 3 mmol/L), nephrocalcinosis, impaired renal function
- Feed intolerance
- Breastfeeding (any) at discharge

Childhood/adulthood outcomes
- Incidence of fracture
- Growth (weight, height, age determined by trialist)
- Neurodevelopmental outcomes (as defined by trialist)

Search methods for identification of studies

Electronic searches
We used the criteria and standard methods of Cochrane and the Cochrane Neonatal Review Group (see the Cochrane Neonatal Group search strategy for specialized register). We conducted a comprehensive search that included the Cochrane Central Register of Controlled Trials (CENTRAL; 2016, Issue 3) in the Cochrane Library; MEDLINE via PubMed (1966 to 14 April 2016); Embase (1980 to 14 April 2016); and the Cumulative Index to Nursing and Allied Health Literature (CINAHL; 1982 to 14 April 2016) using the following search terms: (calcium OR phosphorus) AND (human milk OR breast milk OR breastmilk OR milk), plus database-specific limiters for RCTs and neonates (see Appendix 1 for full search strategies for each database). We applied no language restrictions.

We searched (11 May 2016) clinical trials registries for ongoing and recently completed trials (clinicaltrials.gov; the World Health Organization’s International Trials Registry and Platform www.who.int/ictrp/search/en/; the ISRCTN Registry).

Searching other resources
We searched the reference lists of included trials to identify unpublished and ongoing research.

Data collection and analysis

Selection of studies
For the 2016 update of this review, two review authors (JB, JW) independently examined titles and abstracts identified through electronic and manual searches, retrieved full texts of potential trials for inclusion, examined full texts for eligibility and made decisions on study inclusion or exclusion. A third review author (JH) was available to resolve disagreements.

Data extraction and management
We developed and piloted a data extraction form before gathering data. When available, we extracted data including reference source, eligibility criteria, study methods, participant characteristics, intervention and control details and clinical outcomes. Two review authors independently extracted data (JB, JW) and resolved disagreements by discussion or by referral to a third review author (JH). One review author (JW) entered data into Cochrane statistical software (Review Manager 2013) and a second review author (JB) checked the entered data for accuracy.

Assessment of risk of bias in included studies
Two review authors (JB, JW) independently assessed risk of bias for each study by using the criteria outlined in the Cochrane Handbook for Systematic Reviews of Interventions (Higgins 2011). We encountered no disagreements.

Random sequence generation (checking for possible selection bias)
For each included study, we described the method used to generate the allocation sequence in sufficient detail to allow assessment of whether it should produce comparable groups. We assessed the method as having:
- low risk of bias (any truly random process, e.g. random number table, computer random number generator);
- high risk of bias (any non-random process, e.g. odd or even date of birth, hospital or clinic record number); or
- unclear risk of bias.

Allocation concealment (checking for possible selection bias)
For each included study, we described the method used to conceal allocation to interventions before assignment and assessed whether intervention allocation could have been foreseen in advance of or during recruitment, or changed after assignment. We assessed the method as having:
- low risk of bias (e.g. telephone or central randomisation, consecutively numbered sealed opaque envelopes);
- high risk of bias (open random allocation, e.g. unsealed or non-opaque envelopes, alternation, date of birth); or
- unclear risk of bias.

Blinding of participants and personnel (checking for possible performance bias)
For each included study, we described the methods used, if any, to blind study participants and personnel from which intervention a participant received. We considered studies to be at low risk of bias if they were blinded, or if we judged that lack of blinding would be unlikely to affect results. We assessed the method as having:

- low, high or unclear risk of bias for participants; and
- low, high or unclear risk of bias for personnel.

**Blinding of outcome assessment (checking for possible detection bias)**

For each included study, we described the methods used, if any, to blind outcome assessors from knowledge of which intervention a participant received. We assessed methods used to blind outcome assessment as having low, high or unclear risk of bias.

**Incomplete outcome data (checking for possible attrition bias due to the quantity, nature and handling of incomplete outcome data)**

For each included study, we described completeness of data including attrition and exclusions from analysis. We stated whether attrition and exclusions were reported as well as numbers included in the analysis at each stage (compared with total randomised participants), reasons for attrition or exclusion when reported and whether missing data were balanced across groups or were related to outcomes. When sufficient information was reported, we planned to re-include missing data in the analyses undertaken. We assessed the method as having:

- low risk of bias (e.g. no missing outcome data, missing outcome data balanced across groups); or
- high risk of bias (e.g. numbers or reasons for missing data imbalanced across groups, 'as treated' analysis done with substantial departure of intervention received from intervention assigned at randomisation); or
- unclear risk of bias.

**Other sources of bias**

We described for each included study any important concerns that we had about other possible sources of bias. We assessed whether each study was free of other problems that could put it at risk of bias and assigned each study as follows.

- Low risk of other bias.
- High risk of other bias.
- Unclear risk of other bias.

**Measures of treatment effect**

We used the numbers of events in control and intervention groups of each study to calculate risk ratios (RRs) with 95% confidence intervals (CIs) for dichotomous data. We calculated mean differences (MDs) between treatment groups when outcomes were measured in the same way for continuous data, reported with 95% CIs.

**Unit of analysis issues**

The unit of analysis was the infant.

**Dealing with missing data**

When possible, we carried out analyses on an intention-to-treat basis for all outcomes and analysed all participants in the treatment group to which they were randomised, regardless of the actual treatment received. We attempted to contact the original investigators to request missing data, when possible. When high levels of attrition were observed (> 20%), we had planned to conduct sensitivity analyses to assess the influence of attrition bias. However, with only one included trial, we were unable to assess the effect of attrition bias.

**Assessment of heterogeneity**

We considered whether clinical and methodological characteristics of included studies were sufficiently similar for meta-analysis to provide a clinically meaningful summary. We had planned to do this by assessing statistical heterogeneity using the Chi² test and the I² statistic. We classified heterogeneity as none (< 25%), low (25% to 49%), moderate (50% to 74%) or high (> 75%). We were going to consider an I² measurement greater than 50% and a low P value (< 0.10) in the Chi² test for heterogeneity to indicate substantial heterogeneity (Higgins 2011). We planned that when we detected substantial heterogeneity, we would explore possible explanations by performing sensitivity/subgroup analyses. However, with only one included trial, we were unable to make an assessment of heterogeneity.

**Assessment of reporting biases**

Reporting biases arise when dissemination of research findings is influenced by the nature and direction of results. Some types of reporting bias including publication bias, multiple publication bias and language bias reduce the likelihood that all studies eligible for a review will be retrieved. We aimed to conduct a comprehensive search for eligible studies and looked for duplication of data. We planned to assess publication bias by visually inspecting a funnel plot, if we had identified enough studies (≥ 10 trials). However, with only one included trial, we were unable to assess publication bias.

Two review authors examined the methods of each study for prespecified outcomes. If all prespecified outcomes were reported in the results, we assigned the study low risk of bias. If any prespecified outcomes were not reported in the results, we considered the...
study to carry higher risk of bias. If review authors uncovered reporting bias that could, in their opinion, introduce serious bias, we had planned to conduct a sensitivity analysis to determine the effects of including and excluding these studies in the analysis.

Data synthesis

We evaluated studies for bias, as above, and planned to restrict meta-analysis if bias would be compounded. We had planned to use a fixed-effect meta-analysis to combine data when it was reasonable to assume that studies were estimating the same underlying treatment effects. If evidence of clinical heterogeneity was sufficient to suggest that underlying treatment effects differed between trials, or if we detected substantial statistical heterogeneity, we had planned to undertake sensitivity and subgroup analyses to attempt to explain the heterogeneity. However, with only one included trial, we were unable to perform any meta-analyses.

Quality of evidence

We used the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach, as outlined in the GRADE Handbook (Guyatt 2011a; Guyatt 2011b; Guyatt 2011c; Guyatt 2011d; Guyatt 2011e; Schünemann 2013), to assess the quality of evidence for the following (clinically relevant) outcomes.

- Growth at discharge.
- Bone mineral density (neonatal).
- Fractures (neonatal).
- Growth (childhood).
- Bone mineral density (childhood).
- Fractures (childhood).

Two review authors (JB, JW) independently assessed the quality of the evidence for each outcome above. We considered evidence from RCTs as high quality but downgraded the evidence one level for serious (or two levels for very serious) limitations based on the following: design (risk of bias), consistency across studies, directness of the evidence, precision of estimates and presence of publication bias. We used the GradePro GDT Guideline Development Tool to create a ‘Summary of findings’ table to report the quality of the evidence.

The GRADE approach results in an assessment of the quality of a body of evidence based on four grades.

- High: We are very confident that the true effect lies close to the estimate of effect.
- Moderate: We are moderately confident in the effect estimate: The true effect is likely to be close to the estimate of effect but may be substantially different.
- Low: Our confidence in the effect estimate is limited: The true effect may be substantially different from the estimate of effect.
- Very low: We have very little confidence in the effect estimate: The true effect is likely to be substantially different from the estimate of effect.

We summarised data from selected outcomes in Summary of findings for the main comparison.

Subgroup analysis and investigation of heterogeneity

We planned to perform subgroup analyses to assess effects of calcium supplementation alone, phosphorus supplementation alone and combined supplementation with calcium and phosphorus. Trials were insufficient for subgroup analyses.

Sensitivity analysis

For this 2016 update, we were unable to conduct sensitivity analysis owing to lack of evidence.

RESULTS

Description of studies

Results of the search

For the 2001 review, review authors identified no included studies, excluded 11 studies (Characteristics of excluded studies) and found one study that was awaiting assessment (Characteristics of studies awaiting classification). For this 2016 update, searches yielded 808 potential studies, and we excluded 804 of these. We assessed three studies (four publications) for eligibility. We included one trial (two publications) (Torabi 2014), excluded one (Carroll 2011) and classified one as awaiting assessment (Characteristics of studies awaiting classification). See Figure 1.
Figure 1. Study flow diagram (2016).

- 795 records identified through database searching
- 215 additional records identified through clinical trials databases
- 808 records after duplicates removed
- 808 records screened
- 804 records excluded
- 4 full-text articles assessed for eligibility
- 1 study awaiting assessment
- 1 study excluded as both intervention and control received supplementation
- 1 study (2 publications) included in qualitative synthesis
- 1 study (2 publications) included in quantitative synthesis (meta-analysis)
Included studies

We included one trial (two publications) in this 2016 updated review (Torabi 2014).

- Participants: Investigators randomised 40 infants born before 37 weeks gestation with birth weight below 2.5 kg.
- Setting: The trial was conducted in Iran.
- Interventions and comparisons: Researchers compared breast milk supplemented with calcium, phosphorus and vitamin D versus breast milk and vitamin D only.
- Outcomes: Data showed growth to discharge, bone metabolism and osteopenia. Study authors provided no data on growth at 12 to 18 months, adverse effects, feed intolerance or breastfeeding at discharge and no data on other prespecified childhood/adulthood outcomes of this review (bone metabolism, incidence of fractures).

Excluded studies

Review authors excluded 11 studies in 2001 (Characteristics of excluded studies). We excluded one study for the 2016 update, as both intervention and control groups received supplementation (Carroll 2011).

Risk of bias in included studies

See Figure 2 and Figure 3.
Figure 3. Risk of bias summary: review authors’ judgements about each risk of bias item for each included study.

**Allocation**

**Randomisation**

Torabi 2014 reported that participants were “randomly divided into two groups”; we judged this trial to have unclear risk of bias for randomisation.

**Allocation concealment**

We judged Torabi 2014 to have unclear risk of bias for allocation concealment owing to lack of methodological details.

**Blinding**

**Performance bias**

We judged Torabi 2014 to have unclear risk of performance bias owing to lack of methodological detail.

**Detection bias**

We judged Torabi 2014 to have low risk of detection bias, as outcome assessors were blinded to treatment allocation.
Incomplete outcome data
We judged Torabi 2014 to have low risk of attrition bias, as investigators identified no losses to follow-up.

Selective reporting
Torabi 2014 reported all prespecified outcomes, and we judged the trial to have low risk of reporting bias.

Other potential sources of bias
We identified no other sources of bias.

Effects of interventions
See: Summary of findings for the main comparison  Calcium supplementation compared with no calcium supplementation for preterm infants

Calcium and phosphorus supplementation versus no supplementation

Primary outcomes

Growth to discharge

Weight (grams (g))
Torabi 2014 found no evidence of a difference in weight between infants who received calcium and phosphorus supplementation and those given no supplementation at two weeks (MD 52.50 g, 95% CI -155.44 to 260.44; one RCT; n = 40 infants), four weeks (MD 60.00 g, 95% CI -151.39 to 271.39; one RCT; n = 40 infants) or six weeks (MD 138.50 g, 95% CI -82.16 to 359.16; one RCT; n = 40 infants). We judged the evidence to be of low quality and downgraded the quality for risk of bias (insufficient details to judge randomisation, allocation concealment or blinding of personnel) and imprecision (single small trial).

Length (cm)
Torabi 2014 found no evidence of a difference in length between infants who received calcium and phosphorus supplementation and those given no supplementation at two weeks (MD 0.19 cm, 95% CI -0.42 to 0.80; one RCT; n = 40 infants), four weeks (MD 0.22 cm, 95% CI -0.39 to 0.83; one RCT; n = 40 infants) or six weeks (MD 0.33 cm, 95% CI -0.30 to 0.96; one RCT; n = 40 infants). We judged the evidence to be of low quality and downgraded the quality for risk of bias (insufficient details to judge randomisation, allocation concealment or blinding of personnel) and imprecision (single small trial).

Head circumference (cm)
Torabi 2014 found no evidence of a difference in head circumference between infants who received calcium and phosphorus supplementation and those given no supplementation at two weeks (MD 0.34 cm, 95% CI -1.36 to 2.04; one RCT; n = 40 infants), four weeks (MD 0.47 cm, 95% CI -1.20 to 2.14; one RCT; n = 40 infants) or six weeks (MD 0.77 cm, 95% CI -0.93 to 2.47; one RCT; n = 40 infants). We judged the evidence to be of low quality and downgraded the quality for risk of bias (insufficient details to judge randomisation, allocation concealment or blinding of personnel) and imprecision (single small trial).

Bone metabolism

Serum alkaline phosphatase (ALP) (IU/L)
Torabi 2014 found no evidence of a difference in ALP between infants who received calcium and phosphorus supplementation and those given no supplementation at two weeks (MD -36.35 IU/L, 95% CI -91.14 to 18.44; one RCT; n = 40 infants) or four weeks (MD -34.90 IU/L, 95% CI -81.23 to 11.43; one RCT; n = 40 infants) but found that supplementation was associated with a decrease in serum ALP levels at six weeks postnatal age (MD -56.85 IU/L, 95% CI -101.27 to -12.43; one RCT; n = 40 infants).

Other outcomes of interest (not prespecified)
Torabi 2014 reported osteopenia measured by wrist x-ray at six weeks postnatal age. Data showed no evidence of a difference between infants who received calcium and phosphorus supplementation and those given no supplementation (RR 0.62, 95% CI 0.33 to 1.15; one RCT; n = 40 infants). Researchers provided no data on growth-related outcomes at 12 to 18 months.

Secondary outcomes

Neonatal outcomes
Researchers provided no data on incidence of fracture, adverse effects, feed intolerance or breastfeeding at discharge.
DISCUSSION

Summary of main results

For this updated review conducted in 2016, we included one trial of 40 infants that compared supplementation with calcium and phosphorus versus no supplementation in hospitalised preterm infants. We found no evidence of a difference between infants supplemented with calcium and phosphorus and those given no supplementation for the primary outcomes of this review of growth and bone metabolism, except for a small decrease in alkaline phosphatase (ALP) concentrations at six weeks among infants who received calcium and phosphorus supplementation. Review authors considered this decrease unlikely to be of clinical significance. Evidence was based on the findings of a single small trial, which did not report long-term outcomes for childhood and adulthood (Summary of findings for the main comparison).

Overall completeness and applicability of evidence

High-quality evidence is insufficient to reveal whether supplementation with calcium and phosphorus improved growth and bone health of hospitalised preterm infants. In the single trial included in this review, infants were born relatively large (mean gestation 33 weeks) and therefore were at low risk of metabolic bone disease. These findings may not be applicable to smaller and more preterm infants at greater risk of bone disease who may be more likely to benefit from supplements, if such a benefit can occur. Supplementation with calcium and phosphorus alone is no longer common practice. The Cochrane systematic review on multi-component human milk fortification has provided evidence superseding the evidence provided in this review (Brown 2016).

Quality of the evidence

This updated review includes one trial of 40 infants. The evidence is limited by lack of methodological detail and imprecision. We were not able to make judgements about risk of bias. Evidence was based on data from a single small trial including wide confidence intervals associated with the summary treatment effect. Using GRADE criteria (GradePro GDT), we judged the evidence to be of low quality.

Potential biases in the review process

We have tried to minimise bias in the review process by having two independent review authors conduct data selection and extraction. We double-checked the data entered. We believe that we have conducted a systematic and thorough search of the literature using multiple electronic databases and clinical trials registries without restrictions on language, date of publication or status of publication (published or unpublished).

Agreements and disagreements with other studies or reviews

We identified no other studies or reviews reporting on comparison of calcium and phosphorus supplementation of human milk for preterm infants versus no fortification. Supplementation with calcium and phosphorus alone is no longer common practice, but calcium and phosphorus are commonly included in multi-component human milk fortifiers that are widely used. We refer the reader to the Cochrane review titled “Multi-nutrient fortification of human milk for preterm infants” (Brown 2016).

AUTHORS’ CONCLUSIONS

Implications for practice

Data on supplementation of human milk with calcium and phosphorus are insufficient to allow recommendations for practice.

Implications for research

Supplementation of human milk with minerals, usually as one component of a multi-component fortifier, has become common practice largely on the basis of metabolic studies conducted to evaluate the composition of human milk and the nutritional requirements of preterm infants. Small controlled studies have evaluated urinary excretion of minerals as a proxy for mineral accretion and therefore bone deposition and have provided no evidence of any short-term or long-term clinical benefit derived from mineral supplementation. Despite this, it is unlikely that new studies will evaluate supplementation of human milk with minerals alone
versus no mineral supplementation. Assessment of the effect of supplementation of human milk with minerals may best be done in the context of manipulation of multi-component fortifier composition for very and extremely preterm infants at high risk of metabolic bone disease.

ACKNOWLEDGEMENTS

We would like to acknowledge the contributions of Carl Kuschel and Vazhkudai S Kumaran to the first version of this review in 2001 (Kuschel 1998).

**CONTRIBUTIONS OF AUTHORS**

Jane Harding was an author of the original version of this review. She contributed to the update, interpreted results and provided feedback on versions throughout the process.

Julie Brown was responsible for preparation of drafts of the updated review in 2016. She conducted study selection and data extraction and double-checked data entry.

Jess Wilson conducted study selection and data extraction and double-checked data entry.

**DECLARATIONS OF INTEREST**

None known.
SOURCES OF SUPPORT

Internal sources

• National Women’s Hospital, Auckland, New Zealand.
• University of Auckland, Auckland, New Zealand.

External sources

• Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Department of Health and Human Services, USA.

Editorial support of the Cochrane Neonatal Review Group has been Federally funded by the Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Department of Health and Human Services, USA, under Contract No. HHSN275201600005C

• National Institute for Health Research, UK.

Editorial support for Cochrane Neonatal has been funded by a UK National Institute of Health Research Grant (NIHR) Cochrane Programme Grant (13/89/12). The views expressed in this publication are those of the review authors and are not necessarily those of the NHS, the NIHR or the UK Department of Health.

DIFFERENCES BETWEEN PROTOCOL AND REVIEW

We have updated the text of this review to reflect new methods of reporting for Cochrane reviews and have included the GRADE assessment and Summary of findings for the main comparison. We have expanded methodological aspects of the review as per standard Cochrane Neonatal Review Group procedure.
